

Efficacy, safety, and dose-dependence of the analgesic effects of opioid therapy for people with osteoarthritis: systematic review and meta-analysis

Christina Abdel Shaheed^{1*} , Wasim Awal^{2*} , Geoffrey Zhang³, Stephen E Gilbert⁴, Daniel Gallacher⁵, Andrew McLachlan^{1,6}, Richard O Day^{7,8}, Giovanni E Ferreira⁴, Caitlin MP Jones⁴ , Harbeer Ahedi⁴, Mamata Tamrakar⁴, Fiona M Blyth⁶, Fiona Stanaway¹ , Christopher G Maher^{1,4} 

Osteoarthritis affects more than 500 million people around the world, and it is a leading cause of disability.¹ Non-pharmacological strategies, such as exercise and maintaining a healthy weight, are recommended for first line management, as are simple analgesics, such as non-steroidal anti-inflammatory drugs (NSAIDs) and paracetamol (acetaminophen).² However, advice on using opioid analgesics to treat the pain of knee and hip osteoarthritis is inconsistent;^{3,4} opioids are often prescribed, including for about 40% of people with knee osteoarthritis in the United States.⁵

Systematic reviews of placebo-controlled trials of the effectiveness of opioids for treating osteoarthritis pain have been limited in scope. For example, one evaluated only opioid treatments of at least four weeks' duration,⁶ while a second was restricted to oral opioid therapy.⁷ GRADE ratings were not always reported in the abstract or conclusions, and the validity of opioid dose-response analyses were sometimes unclear.⁸ One review excluded tramadol because it had been examined in a separate review.⁹

We therefore undertook a systematic review to provide a comprehensive evaluation of the efficacy and safety of opioid analgesic therapy regimens for people with osteoarthritis, and to explore dose-effect relationships.

Methods

We searched MEDLINE, EMBASE, the Cumulative Index to Nursing and Allied Health Literature (CINAHL), PsycINFO, the Allied and Complementary Medicine Database (AMED), the Cochrane Database of Systematic Reviews, and the Cochrane Central Register of Controlled Trials (CENTRAL) for eligible randomised controlled trials (RCTs) published in any language in peer-reviewed journals to 31 October 2020 (Supporting Information, table 1). To avoid overestimating treatment effects,¹⁰ we also searched the World Health Organization International Clinical Trials Registry (<https://trialsearch.who.int>) for unpublished trials. We screened the reference lists of retrieved publications to identify further RCTs. Our systematic review was prospectively registered with PROSPERO (CRD420191142813; 16 October 2019).

Inclusion criteria

We included RCTs in which the analgesic effect of an opioid was compared with that of placebo in people with osteoarthritis of any type (knee, hip, hand, spine) of any duration. All single ingredient and combination opioid-containing analgesic regimens were included, regardless of opioid dose and administration route. We did not include trials in which the effect of opioid therapy

Abstract

Objective: To evaluate the efficacy and safety of opioids for analgesic therapy for people with osteoarthritis.

Study design: Systematic review and meta-analysis of randomised, placebo-controlled trials of opioid therapies for treating the pain of osteoarthritis. The primary outcome was medium term pain relief (six weeks to less than 12 months). Quality of evidence was assessed with GRADE criteria.

Data sources: MEDLINE, EMBASE, the Cochrane Database of Systematic Reviews and Central Register of Controlled Trials, CINAHL, PsycINFO, AMED, and the WHO International Clinical Trials Registry; trials published to 31 October 2020.

Data synthesis: We extracted pain, disability, health-related quality of life, and adverse events data for 36 eligible trials (overall dose range: 10–210 oral morphine milligram equivalents [MME] per day). Continuous pain and disability outcomes were converted to common 0–100-point scales; changes of less than ten points were deemed to be very small effects. Differences in dichotomous outcomes were expressed as risk ratios. Data were pooled for meta-analysis in random effects models. The evidence from 19 trials (8965 participants; dose range, 10–126 MME/day) for very small medium term pain relief (mean difference [MD], –4.59 points; 95% CI, –7.17 to –2.02 points) was low quality, as was that from 16 trials (6882 participants; dose range, 10–126 MME/day) for a very small effect on disability (MD, –4.15 points; 95% CI, –6.94 to –1.35 points). Opioid dose was not statistically significantly associated with either degree of pain relief or incidence of adverse events in a meta-regression analysis. Evidence that opioid therapy increased the risk of adverse events (risk ratio, 1.43; 95% CI, 1.29–1.59) was of very low quality.

Conclusions: Opioid medications may provide very small pain and disability benefits for people with osteoarthritis, but may also increase the risk of adverse events.

PROSPERO registration: CRD42019142813 (prospective).

was compared with other treatments but not with placebo. Trials including a range of pain conditions were eligible if data for participants with osteoarthritis could be extracted.

Study selection

Three authors (CAS, WA, GZ) independently screened the titles and abstracts and read the full text of potentially eligible publications; disagreements were resolved by consensus.

Data extraction and management

Two authors from a pool of four authors (WA, GZ, CAS, SEG) independently extracted study and participant characteristics

* Equal first authors.

⁷St Vincent's Hospital, Sydney, NSW. ⁸St Vincent's Clinical School UNSW, Sydney, NSW. [✉ christina.abdelshaheed@sydney.edu.au](mailto:christina.abdelshaheed@sydney.edu.au) • doi:10.5694/mja2.51392

and outcomes data. They also assessed the risk of bias with the Cochrane Collaboration tool;¹¹ each of the seven risk items were rated high, low, or unclear. Disagreements were resolved by consensus.

The major outcome of interest was pain intensity measured using a visual analogue scale, numeric rating scale, or other continuous measure. We also extracted data on disability (Western Ontario and McMaster Universities Osteoarthritis Index [WOMAC] physical function scale), health-related quality of life (36-item Short Form health survey [SF-36], the European Quality of Life scale, or the Patient Generated Index), and adverse events.

Outcomes were classified as immediate (follow-up less than two weeks after randomisation), short (two to less than six weeks), medium (six weeks to less than 12 months), or long term (12 months or more). The primary outcome for our analysis was medium term pain relief.

Continuous outcomes were converted to a 0–100 scale, and we report mean differences (MDs) in outcomes (not standardised mean differences) with 95% confidence intervals (CIs). We classified between-group differences of 0–9 points as very small, 10–19 points as small, 20–29 points as moderate, and differences of 30 points or more as large. If authors reported both mean follow-up and mean change scores, we report the follow-up mean scores and standard deviations (SDs) if the baseline group scores were similar. For dichotomous outcomes, we report relative risks (RRs) with 95% CIs.

We extracted data for adverse events, and the numbers of trial participants receiving opioid therapy who withdrew during the run-in (for enriched trial designs) or trial phases because of adverse events or lack of efficacy, or who were lost to follow-up. Missing data were imputed using methods described in the Cochrane handbook for systematic reviews.¹²

We assessed trial heterogeneity (in terms of the characteristics of participants, interventions, outcome measures, and timing of outcome measurement) by visual inspection of forest plots and with the I^2 statistic.

Statistical analyses were conducted in R 4.0.3 (R Foundation for Statistical Computing) and R Studio 1.2.1093 (<https://www.rstudio.com/products/rstudio/>).

Data synthesis

We pooled outcomes data using restricted maximum likelihood estimation in random effects meta-analysis models. Three-level mixed effects models (fitted in R with the *metafor* 3.0-1 package¹³) accounted for the non-independence of effect sizes from the same study or comparator group, and assumed a compound symmetry covariance structure.

We used meta-regression in the same three-level models to evaluate associations of opioid dose with medium term impact on pain and adverse events. Single ingredient opioid analgesic doses were converted to oral morphine milligram equivalent (MME) doses¹⁴ and log-transformed prior to meta-regression.

In our primary meta-analysis, we assessed the pooled effects of all single ingredient opioid analgesics. In a separate analysis, we calculated treatment effect sizes for combination analgesics including an opioid and a simple analgesic (paracetamol or NSAID).

Quality of evidence

We used the Grading of Recommendations, Assessment, Development and Evaluations (GRADE) criteria¹⁵ to evaluate the

overall quality of evidence. Quality of evidence was downgraded one level for each of four factors:

- limitation in study design: the risk of bias was high (one or more domains were judged to be at high risk) for more than one-quarter of studies included in an analysis;¹¹
- inconsistency of results: statistical heterogeneity was large ($I^2 > 50\%$);¹⁶
- imprecision: confidence interval width was greater than ten points (continuous outcomes) or included zero (dichotomous outcomes); and
- publication bias: assessed by funnel plot analysis or with the Egger regression test¹⁷ (for ten or more studies).

Overall quality of evidence was classified as high, moderate, low, or very low ([Supporting Information](#), table 2).¹³

Sensitivity analyses

We conducted sensitivity analyses that assessed the impact on treatment effects of opioid formulation (modified or immediate release preparations) and study design (standard or enriched), to compare the effects of tramadol with those of other opioids, and to assess the effects of industry funding, trial report type (peer-reviewed publication or unpublished), and the use of rescue medication.

Protocol amendments after PROSPERO registration

We conducted sensitivity (rather than subgroup) analyses of the effects of formulation and study design. The tramadol sensitivity analysis was added because the medication is recommended by some guidelines for people with osteoarthritis.⁴ The sensitivity analyses of the effects of industry funding, trial report (peer-reviewed publication or unpublished), and the use of rescue medication were added after PROSPERO registration.

Results

We initially identified 2286 relevant publications, of which 74 were deemed potentially eligible after abstract review; 38 were excluded after reviewing the full text, and 36 publications (all in English) were included in our analysis¹⁸⁻⁵³ ([Box 1](#); [Supporting Information](#), tables 3 and 4).

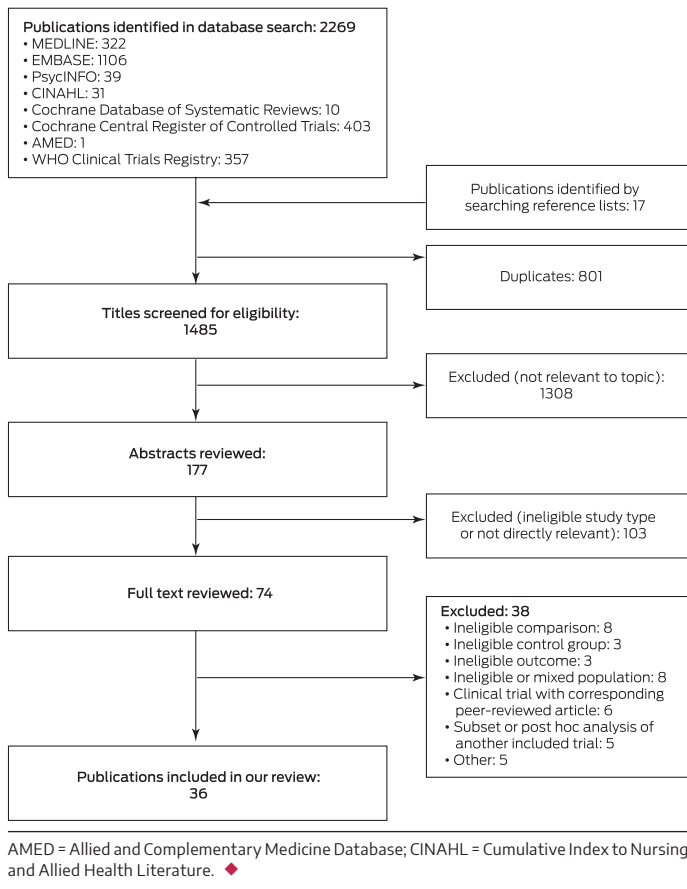

Study participants

The eligible trials included people with high pain levels; the median score at baseline for all included trials was 72.0 points (interquartile range [IQR], 61.7–75.8 points). A median of 42% of participants in all opioid trial arms (IQR, 33–52%) and of 40% of participants in the control arms (IQR, 24–48%) discontinued participation during trial phases. The most frequent reasons for withdrawal from the opioid arms were adverse events (median, 24% of participants; IQR, 15–30%), lack of efficacy (median, 7.8%; IQR, 3.8–11%), and other reasons (loss to follow-up, protocol violation: median, 6.8%; IQR, 3.6–12%) ([Supporting Information](#), table 5 and figure 1).

Treatment regimens

The included studies evaluated oral or transdermal opioid analgesic medications (modified release formulations) for people with osteoarthritis, chiefly of the knee, hip, or both. The opioid analgesics evaluated were tramadol, oxycodone, tapentadol, hydromorphone, codeine, buprenorphine, fentanyl, oxymorphone, tramadol/

1 Selection of publications for inclusion in our analysis

acetaminophen, oxycodone/acetaminophen, and ibuprofen/codeine; five studies evaluated transdermal buprenorphine or fentanyl.^{34-36,43,45} Doses ranged from 10 to 210 MME per day, treatment duration from one day (200 mg ibuprofen/30 mg codeine, for hip osteoarthritis) to 12 weeks; 15 studies^{18-22,24,25,28,29,31,33,35,39,41,45} reported treatment durations of four weeks or less, with regular (ie, not “when required”) regimens (Supporting Information, tables 3 and 6).

Trial characteristics

For all but two studies^{25,28} the risk of bias was rated as high (Supporting Information, table 7). The longest follow-up period was 16 weeks;⁵¹ 19 trials had follow-up periods of 12 weeks.^{23,26,27,30,32,36-38,40,42-44,46-51,53} Treatment duration was usually the same length as the follow-up period (Supporting Information, table 3). Four trials^{36,37,44,47} had enrichment trial designs, whereby patients who completed an open label run-in phase during which they tolerated and responded to the opioid medication were included in the trial phase.

Treatment effects: pain

For the primary outcome (medium term pain relief), the evidence from 19 trials^{23,26,30,32,34,36-38,40,42-44,46,48-53} (8965 patients; dose range, 10–126 MME/day) for a very small effect (MD, –4.59 points; 95% CI, –7.17 to –2.02 points) was low quality (Box 2; Supporting Information, table 8). There was moderate quality evidence from 13 trials^{19,21,22,24,26,28,29,32,34,42,48,50,53} (5320 patients; dose range, 10–126 MME/day) for a very small immediate effect (MD, –4.90 points; 95% CI, –6.46 to –3.34 points), and from 19 trials^{20-22,24,26,28-35,41,42,45,48,50,53} (6949 patients; dose range, 10–210 MME/

day) for a very small short term effect (MD, –6.38 points; 95% CI, –8.45 to –4.30 points) (Supporting Information, tables 8 and 9; figures 2 and 3).

Four studies^{18,20,25,27} compared the effects of combinations of opioids and simple analgesics with that of placebo. Moderate quality evidence suggested that 6 × 200 mg ibuprofen/30 mg codeine per day has a small effect in the immediate term on hip osteoarthritis pain (MD, –19.0 points; 95% CI, –31.2 to –6.8 points),¹⁸ and low quality evidence that tramadol/acetaminophen provides very small pain relief in the immediate²⁵ and medium terms.^{25,27} Low quality evidence from one trial²⁰ suggested that 4 × 5 mg oxycodone (immediate release)/325 mg acetaminophen per day provides small short term pain relief (MD, –17.0 points; 95% CI, –30.3 to –3.72 points).

Treatment effects: disability

Evidence from 16 trials^{23,26,30,32,34,38,40,42-44,46,48-51,53} (6882 patients; dose range, 10–126 MME/day) for a very small medium term effect on disability as assessed with the WOMAC physical function scale (MD, –4.15 points; 95% CI, –6.94 to –1.35 points) was low quality. There was moderate quality evidence from three trials^{24,32,46} (2105 patients; dose range, 10–40 MME/day) for a very small immediate effect (MD, –4.11 points; 95% CI, –6.92 to –1.30 points), and from eight trials^{21,24,30-33,46,50} (3394 patients; dose range 10–210 MME/day) for a very small short term effect (MD, –5.84 points; 95% CI, –7.90 to –3.79 points) (Box 3; Supporting Information, tables 8 and 10). The effect of opioids on WOMAC total score was very small at each time point (Supporting Information, tables 8 and 11).

Treatment effects: quality of life

Opioids had no statistically significant effect on mean SF-36 mental component scores in the short and medium terms. They had a very small effect on the SF-36 physical component score in the short term (two trials;^{31,33} 824 patients; MD, 3.05 points; 95% CI, 1.13–4.97 points) and medium term (five trials;^{32,34,42,46,50} 3525 patients; MD, 0.70 points, 95% CI, 0.04–1.37 points). Only one study³⁰ (107 patients) found a favourable medium term effect of controlled-release oxycodone on quality of life (76 MME/day) measured with the Patient Generated Index (MD, 11.5 points; 95% CI, 2.37–20.6 points) (Supporting Information, tables 8 and 12).

Adverse events

There was very low quality evidence from 16 studies^{26,30,32,34,36,38,40,42-44,46,48-51,53} (8482 patients) that opioids (dose range, 10–126 MME/day) increased the risk of adverse events at medium term follow-up (*v* placebo: RR, 1.43; 95% CI, 1.29–1.59). In these 16 studies, 3871 of 5349 people in the opioid arms (72.4%) and 1560 of 3133 in the control arms (49.8%) had experienced adverse events, most frequently gastrointestinal events (nausea, vomiting, constipation, diarrhoea); other common side effects were dry mouth, fatigue, pruritus, somnolence, dizziness, and headache (Supporting Information, tables 8, 13, 14; figure 4). In five trials that compared tramadol with placebo,^{26,32,38,40,46} 1493 of 2192 people in the tramadol arms (68.1%) and 469 of 981 in the placebo arms (47.8%) reported adverse events (RR, 1.34; 95% CI, 1.22–1.48).

Meta-regression analyses

In meta-regression analyses, the associations of log(MME dose) with pain relief (19 trials;^{23,26,30,32,34,36-38,40,42-44,46,48-53} 8965 patients;

2 Medium term effects of opioid medications on pain in people with osteoarthritis pain: estimated mean differences (MDs) with 95% confidence intervals (CIs)*

regression coefficient, 0.92; 95% CI, -6.58 to 8.41) and adverse events at medium term follow-up (16 trials^{26,30,32,34,36,38,40,42-44,46,48-51,53}; 8482 patients; regression coefficient, 0.08; 95% CI, -0.17 to 0.33) were not statistically significant (Box 4; Supporting Information, table 8). The evidence for these findings was of very low quality.

Sensitivity analyses

Sensitivity analyses indicated that the medium term effects of tramadol on pain (-8.13 points; 95% CI, -11.8 to -4.51 points) and disability (-7.44 points; 95% CI, -12.7 to -2.16 points respectively) were statistically significant, as were the medium term effects

3 Medium term effects of opioid medications on disability in people with osteoarthritis: estimated mean differences (MDs) with 95% confidence intervals (CIs)*

CR = controlled release; ER = extended release; IR = immediate release; PR = prolonged release.* $I^2 = 76\%$. ◆

4 Meta-regression of the relationships between the log-transformed morphine milligram equivalent (MME) dose and medium term pain treatment effect (A) and adverse events (B)*

* Each circle represents an eligible comparison in the included publications (the number of comparisons exceeded the total number of publications for each outcome); circle size is proportional to sample size. The dashed lines enclose the 95% confidence region. The regression equations are: $Y = -6.0 + 0.92 \cdot \log(\text{MME dose})$ (A); $Y = 0.23 + 0.08 \cdot \log(\text{MME dose})$ (B). ◆

of immediate release preparations on pain (-9.50 points; 95% CI, -19.0 to -0.04 points); the effects, however, were very small (Supporting Information, table 15).

Discussion

We found moderate to low quality evidence that opioid medications have very small effects on pain and disability in people with osteoarthritis up to three months after the initiation of therapy. The incidence of adverse events, including gastrointestinal and central nervous system effects, was higher for people receiving opioids than for those receiving placebo, but evidence that opioids increase the risk of adverse events in the medium term was of very low quality. Meta-regression did not indicate a significant association between opioid medication dose (range, 10–126 MME/day) and pain relief or the incidence of adverse events at medium term follow-up.

Our review is the first systematic review of therapy for people with osteoarthritis to conclude that single ingredient opioid medications provide very small immediate, short, and medium term benefits, and that opioid dose (in the range examined) may not influence pain relief in the medium term. This is in contrast to conventional thinking that higher doses are more beneficial, and our findings should discourage the prescribing of stronger opioid analgesics (ie, higher MME equivalence) for people with severe osteoarthritis pain. Given their very small effects, the appropriateness of single ingredient opioids for managing osteoarthritis is debatable. Our findings also indicate that the association between opioid dose and medium term risk of adverse events is unclear.

However, combinations of low dose opioids with simple analgesics may have beneficial synergistic effects. For example, the 95% confidence intervals for the pain relief achieved by low dose codeine with ibuprofen and low dose oxycodone with acetaminophen included large effects (more than 30 points). For some people with osteoarthritis, short term use of these combination analgesics may be a reasonable option; however, this finding was based on a small number of studies.

The pattern of prescribing during the first month of opioid therapy is critical for the future risk of persistent use, which

is particularly high for long-acting opioid preparations.⁵⁴ As many as 25% of people with osteoarthritis who commence opioid analgesic therapy are still taking them one year later.⁵⁵ Another problem is that osteoarthritis, as a chronic disease, is often treated with modified release opioid preparations; 26 studies included in our review evaluated such preparations. Modified release preparations are taken regularly to moderate the variation between peak and trough levels, providing more consistent pain relief. As they are typically taken “regularly to control pain”⁵⁶ rather than as required, it can be very difficult for patients to stop using them.⁵⁴

Guideline recommendations regarding the use of opioids for treating osteoarthritis pain are inconsistent. Our findings indicate that opioids provide pain relief similar to that of paracetamol,⁵⁷ and their benefit is almost half that achieved by NSAIDs (a conclusion, however, based on indirect comparisons),⁵⁸ challenging beliefs that simpler analgesics are less effective than opioids for people with common musculoskeletal conditions.

Strengths and weaknesses

Our systematic review is the largest and most comprehensive of opioid therapy for osteoarthritis pain. The most recent review of this topic, for instance, included only 18 trials.⁷ Earlier reviews have excluded tramadol studies,⁹ evaluated only oral preparations,⁸ or included only treatment regimens of more than one month.⁶ Further, review authors have generally reported outcomes as standardised mean differences (ie, proportions of standard deviations), whereas we present mean differences on a common 0–100 pain scale to facilitate easier interpretation by clinicians and patients.

However, study heterogeneity was high for the assessments of some effects. Opioid regimens ranged from one day to 12 weeks in duration, and dosage from 10 to 210 MME/day. Further, risk of bias was high for all but two trials,^{25,28} and some trials had enrichment design that may have led to more optimistic effect estimates, as only participants who responded to and tolerated the medicine during the run-in phase entered the main trial phase. Enrichment trial designs and high participant withdrawal rates during main trial phases meant that our effect estimates

are based upon outcomes for about half of the participants who entered these trials. Finally, most of the included studies were undertaken in the United States, and country-specific ethnic, cultural, or health service features may have influenced outcomes.

Conclusion

Opioid medications may provide people with osteoarthritis very small benefits but also may increase the risk of adverse events. The association between opioid dose, pain relief, and risk of adverse events requires further evaluation. Alternative pain management strategies for people with osteoarthritis should be investigated, as well as opioid-sparing and tapering strategies for those being treated with opioids.
